ABSTRACT

We present and analyze the first high-resolution hard X-ray spectra from a solar flare observed in both X-ray/$\gamma$-ray continuum and $\gamma$-ray lines. The 2002 July 23 flare was observed by the Ramaty High Energy Solar Spectroscopic Imager (RHESSI). The spatially integrated photon flux spectra are well fitted between 10 and 300 keV by the combination of an isothermal component and a double power law. The flare plasma temperature peaks at 40 MK around the time of peak hard X-ray emission and remains above 20 MK 30 min later. We derive the evolution of the nonthermal electron density distribution by directly fitting the RHESSI X-ray spectra with the thick-target bremsstrahlung from a double power-law electron distribution with a low-energy cutoff. We also derive the evolution of the mean electron flux, which does not assume thick-target emission. We find that the injected nonthermal electrons are well described throughout the flare by a double power-law distribution with a low-energy cutoff that is typically on the order of 20–40 keV. We compare the energy content of the thermal flare

plasma observed by RHESSI and GOES with the energy contained in the non-thermal electrons. We find that the total energy deposited into the flare plasma by nonthermal electrons is on the order of and possibly less than the energy in the thermal plasma observed by GOES and RHESSI. However, these fits do not rule out the possibility that the energy in nonthermal electrons exceeds the energy in the thermal plasma.

Subject headings: Sun: flares, Sun: X-rays, gamma rays

1. Introduction

Since its launch on 2002 February 5, the Ramaty High Energy Solar Spectroscopic Imager (RHESSI) has been obtaining unprecedented images and spectra of solar flares in hard X-rays and $\gamma$-rays (see Lin et al. 2000 for a description of the RHESSI instrument and its capabilities). The hard X-ray/$\gamma$-ray continuum traces energetic electrons accelerated in flares, while $\gamma$-ray lines trace accelerated ions (e.g., Hudson & Ryan 1995). The first (and, currently, the only) $\gamma$-ray line flare observed by RHESSI occurred on 2002 July 23. This observation provides a rare opportunity to compare electron and ion acceleration in a single flare.

This Letter focuses on electrons in the July 23 flare. Spatially integrated photon flux spectra are derived from the RHESSI data in the 10 keV – 300 keV energy range. These spectra are fitted with computations of the bremsstrahlung flux from model electron distribution functions to deduce the temporal evolution of the flare electrons. Hard X-ray images and imaged spectra are obtained and analyzed in Krucker et al. (2003) and Emslie et al. (2003), respectively. The flare $\gamma$-ray bremsstrahlung above 300 keV is discussed in Share et al. (2003). A comprehensive summary of the flare observations and their implications is presented in Lin et al. (2003).

We obtain the hard X-ray spectra and their time evolution in Section 2. In Section 3 we derive mean electron flux distributions (Brown, Emslie & Kontar 2003) from the RHESSI spectra. These distributions are independent of the thick-target assumption and, therefore, are well suited for comparison with electron distributions computed from theoretical flare models. Our mean electron distributions, obtained through forward fitting, are compared with mean electron flux distributions obtained through direct inversion in Piana et al. (2003). In Section 4, assuming that the emission is thick-target bremsstrahlung, we obtain the evolution of the electron density distribution. We use these density distributions to compute the electron energy flux and its time evolution, and the total energy in accelerated electrons.
These are compared to the evolution of the energy content of the thermal plasma observed by RHESSI and GOES. Our results are discussed in Section 5.

2. X-Ray Spectra

The time history of the flare emission in three energy bands is shown in Figure 1a. RHESSI uses two attenuators, a thin aluminum shutter and a thick aluminum shutter, to avoid saturating the detectors during large flares. The July 23 flare was observed in two attenuator states. The instrument was primarily in the A3 state, with both attenuators in place. Early in the flare before 00:26:08 UT and late in the flare after 00:59:21 UT the instrument was in the A1 state, with only the thin attenuator in place. There were also four brief periods during which the instrument switched from A3 to A1 and back to A3. These transitions in attenuator state are apparent in the time history of the lowest energy band in Fig. 1a. The flux calibration is currently uncertain during the four brief transition periods. These time periods appear as gaps in subsequent results derived from the data.

Spectral fits were obtained using the Solar Software Tree (SSW) spectral analysis routine (SPEX, see Schwartz 1996, Smith et al. 2003). Before fitting the data, we corrected the observed counts for pulse pileup and decimation. Background counts were subtracted from the data by obtaining a linear fit through the background levels before and after the flare. Because the attenuators substantially diminish the photon flux that reaches the RHESSI detectors at low energies, spectra obtained in the A1 state were fitted down to 10 keV photon energies while spectra obtained in the A3 state were fitted down to 15 keV. The spectra were fitted up to 300 keV unless a contribution from background counts was significant below this energy. At times earlier than 00:26:00 UT, for example, spectral fits could not be obtained above 60 keV. For photon fluxes well above the background, we estimate the uncertainty in the fluxes to be 2% in the A3 state and 5% in the A1 state. The absolute uncertainty in the RHESSI fluxes is currently not known. These estimates were obtained by requiring the normalized $\chi^2$ for our spectral fits to be on the order of one (rather than much less than one).

The count spectra in each 20-s time interval were fitted with the combination of an isothermal bremsstrahlung spectrum and a double-power-law photon spectrum. This provides six fit parameters: the temperature ($T$) and emission measure ($EM$) of the isothermal component, lower ($\gamma_L$) and upper ($\gamma_U$) spectral indices and the energy at which the spectral break occurs ($E_B$), and the normalization for the double-power-law spectrum, taken to be the photon flux at 50 keV ($F_{50}$). Late in the flare, only the isothermal component is evident. During the early rise of the flare (A1 state) we found that the spectra could be fitted with
a double power law alone. An equally good fit could be obtained with the combination of an isothermal component and a double power law above $\sim 18$ keV. The results of this fit are shown in Fig. 1. Since this thermal component is not required by the data, the temperatures and emission measures derived from these fits are not as well established as those derived from fits to later time intervals when the thermal component is visually apparent in the spectra (as in Fig. 3).

The time history of the temperature of the isothermal component is shown in Fig. 1b (plus signs). The temperature rapidly rises to “superhot” values (Lin et al. 1981) as high as 40 MK. This hot thermal emission is consistent with the spectrum of the “coronal” source observed in RHESSI images (Emslie et al. 2003). The plasma gradually cools after the end of the first peak in the flare emission, with some reheating in subsequent peaks. Temperatures derived from GOES data are shown for comparison (solid curve). Throughout the flare the temperatures derived from the RHESSI data are typically around 10 MK higher than those derived from the GOES data. Thirty-seven minutes after reaching its peak value of 40 MK, the plasma temperature derived from the RHESSI spectra remains above 20 MK.

The emission measure of the isothermal component is plotted in Fig. 1c (plus signs). Although the peak temperature is similar to that obtained by Lin et al. (1981) for the 1980 June 27 flare, the peak emission measure is thirty times greater. The GOES emission measure (solid curve, scaled by a factor of 0.25) always exceeds the RHESSI emission measure, as expected for lower temperature plasma.

The spectral indices $\gamma_L$ and $\gamma_U$, defined by Flux $\propto E^{-\gamma}$, have values between 2.5 and 3.5 throughout most of the flare (Fig. 1d). These spectral indices and their time evolution are consistent with the spectra obtained for the “footpoint” sources observed in RHESSI images (Emslie et al. 2003). Earlier in the flare, before the impulsive rise, the spectral indices are much greater, on the order of 4.5 to 7. While $\Delta \gamma$ is on the order of one or two before the impulsive rise, it is subsequently on the order of 0.5 or less. When the nonthermal spectrum is observable after 00:40:00 UT, it is best fit with a single power law. The break energy, plotted in Fig. 1e, increases from values below 50 keV before the impulsive rise of the flare to values in the range 70–125 keV.

Fig. 1f shows the time history of the photon flux at 50 keV. This closely follows the 40–100 keV light curve.
3. Mean Electron Flux Distributions

The mean electron flux is the spatially averaged value of the electron flux weighted by the plasma density (Brown et al. 2003). Deducing the mean electron flux from a photon spectrum is equivalent to deducing the electron flux under the assumption that the radiation is thin-target bremsstrahlung. In this paper we compute the mean electron flux distribution for time intervals during the rise and main peak of the flare (20 s integration times). We do this by assuming that the functional form of the mean electron flux is a double power law with a low-energy cutoff. We fit the spectral data with the bremsstrahlung spectra computed from this distribution and an isothermal distribution. The results are shown in Figure 2. The derived temperatures and emission measures are not shown here, since they are similar to the values in Fig. 1. For these and subsequent computations in Section 4, the bremsstrahlung cross section of Haug (1997) is used with the Elwert (1939) correction.

As expected for thin-target bremsstrahlung, the power-law indices for the mean electron flux distribution (Fig. 2b) are smaller than the photon spectral indices (Fig. 1d) by about 1. The break energies for the electron distributions (Fig. 2c) are higher than those for the photon spectra (Fig. 1e) because the photons are produced by electrons with higher energies than the photon energy. The bremsstrahlung spectrum only begins to flatten at energies immediately below the break in the electron distribution. The photon spectrum flattens to about $E^{-1}$ below the low energy cutoff, $E_c$, shown in Fig. 2d. The values for $E_c$ were determined by allowing the fitting routine to find the highest value consistent with a minimum $\chi^2$ fit. The normalization in Fig. 2e is $\bar{n}V\bar{F}$, where $V$ is the volume of the emitting region, $\bar{n}$ is the mean density in the emitting volume, and $\bar{F}$ is the mean electron flux distribution integrated from $E_c$ to the highest electron energy in the distribution.

The spectral fit for the interval 00:30:00–00:30:20 UT is shown in the top panel of Figure 3. The residuals from this fit, defined as $(F_{\text{obs}}(E) - F_{\text{fit}}(E))/\sigma(E)$, where $E$ is the photon energy, $F_{\text{obs}}$ is the observed photon flux, $F_{\text{fit}}$ is the photon flux given by the model at energy $E$, and $\sigma$ is the uncertainty in the observed flux, are plotted in the bottom panel. The residuals are limited to about the $\pm 2\sigma$ level, but they are not entirely random. The systematic deviation below 20 keV may be due to our currently uncertain knowledge of the steep RHESSI response function at low energies when both attenuators are in place, or to the contribution of lower temperature plasma to the thermal bremsstrahlung. An inaccurate background subtraction could explain any systematic trend above 200 keV. Of particular physical interest is the oscillation between 20 keV and 50 keV. This may indicate that our correction for pulse pileup is not entirely correct. On the other hand, this oscillation might be associated with X-ray photons Compton scattered in the photosphere (albedo) or partial ionization in the interaction region. These possibilities are considered by Alexander & Brown
(2003) and Kontar et al. (2003), respectively.

Piana et al. (2003) derive mean electron flux distributions from this flare data using a direct inversion technique. Their results are quite different from the double power-law distributions obtained here, showing considerably more structure in the electron distributions. Both distributions provide a good fit to the photon spectra. The differences in these derived electron distributions highlight the fact that there is generally not a unique electron distribution associated with an observed photon spectrum. Nevertheless, the spectral fits can rule out many models, and RHESSI’s combination of high spectral and spatial resolution allows us to test physical processes and models that could not be adequately addressed with previous observations.

4. Electron Density Distributions and Energetics

Electron density distributions are computed assuming that the emission is thick-target bremsstrahlung (Brown 1971) and that the electron distribution is a double power law with a low-energy cutoff. The thick-target bremsstrahlung from this electron distribution is numerically computed and, with the isothermal component included, best fits to the RHESSI spectra are obtained. The low-energy cutoff, as for the mean electron flux distribution, is allowed to take the highest value consistent with a minimum $\chi^2$ fit. The results are shown in Figure 4. Note that the electron flux distribution can be derived from the density distribution by multiplying the density distribution by the electron speed.

The upper power-law indices (triangles, Fig. 4b) are larger by about 1.5 than the upper photon spectral indices, as expected ($\delta_u \approx \gamma_u + 1.5$). The lower power-law indices are only steeper by about 1, however, because fewer electrons are present above the break energy than would have been present for a single power law. The upper power-law index throughout much of the flare of about 4.5 is consistent with the value estimated from radio observations (White et al. 2003). The break energy (Fig. 4c) increases with time from values around 30 keV to values in excess of 200 keV. The low-energy cutoff (Fig. 4d) increases from around 20 keV before 00:26:00 UT to 30–40 keV after this time. For a brief period between 00:40:40 UT and 00:42:20 UT the spectra were best fit with a single power law and a low-energy cutoff as high as 73 keV.

The distributions before 00:26:00 UT are also consistent with a double power law alone (no isothermal component) and a single power law with a high energy cutoff that increases from 40 keV at early times to as high as 100 keV at later times. We found that these spectra could not be adequately fit with a single power law with a low-energy cutoff (no isothermal
component) or with an isothermal distribution alone, however.

The normalization for the double power-law electron density distribution plotted in Fig. 4e is the total density of nonthermal electrons above $E_c (n)$ times the area of the thick-target interaction region ($A$). For an area of $10^{19} \text{ cm}^2$, on the order of that shown by the RHESSI image at 00:25:40 UT (see Krucker et al. 2003), this gives a density in suprathermal electrons of $6 \times 10^7 \text{ cm}^{-3}$ at 00:25:20 UT, when $nA$ is at its maximum value. Later in the flare the observed nonthermal source area is as low as $10^{17} \text{ cm}^2$, giving values of $n$ that are up to an order of magnitude higher. White et al. (2003), in interpreting their radio observations of the flare, deduce a nonthermal electron density of $10^{11} \text{ cm}^{-3}$ above 10 keV at 00:35:00 UT. We obtain a density of $3 \times 10^9 \text{ cm}^{-3}$ at this time if the distribution extends down to 10 keV. Most of difference in these densities can be attributed to the flattening of the electron distribution below 134 keV in our fit. If this flattening were not present, the electron density above 10 keV would be $2.4 \times 10^{10} \text{ cm}^{-3}$.

The total accumulated energy deposited into the flare plasma by electrons with energies above $E_c$ is plotted as a function of time in Fig. 4f (dotted curve). This is obtained by integrating the electron flux distribution derived for each 20 s interval, $n(E)vA$, over all energies above $E_c$, multiplying by the time interval (20 s) and obtaining the sum of these energies up to the time of interest. About two-thirds of this energy is deposited before 00:26:00 UT. The total energy injected by these electrons is found to be $2.6 \times 10^{31} \text{ erg}$.

The energy contained in the thermal plasmas observed by RHESSI (dot-dash line) and by GOES (solid line) is also plotted in Fig. 4f. Using the temperature and emission measure derived from the observations, we are able to compute the product of the plasma density and energy, $n(3nkT V)$. We estimate the volume of the coronal source observed during the main phase of the flare (see Krucker et al. 2003) to be $4 \times 10^{27} \text{ cm}^3$. For an emission measure of $5 \times 10^{49} \text{ cm}^{-3}$ from Fig. 1c, we obtain a density of $1 \times 10^{11} \text{ cm}^{-3}$ for the hot plasma observed by RHESSI. We therefore plot the thermal energies for a constant density of $10^{11} \text{ cm}^{-3}$. The energy is higher for a plasma density smaller than $10^{11} \text{ cm}^{-3}$, and lower for a density greater than $10^{11} \text{ cm}^{-3}$.

We see from Fig. 4f that, even with the low-energy cutoffs derived here, the accumulated energy in the nonthermal electrons is comparable to the energy in the plasma observed by both RHESSI and GOES. The energy deposited by the nonthermal electrons may be somewhat less than the energy in the thermal plasma if the density of the plasma observed by GOES is less than $10^{11} \text{ cm}^{-3}$. Otherwise, the energy is equal to or exceeds the thermal energy. We find the total energy deposited by the nonthermal electrons to be $2.6 \times 10^{31} \text{ erg}$.

Electron distributions with low-energy cutoffs lower than the values derived here are
also consistent with the RHESSI spectra. Therefore, the energy deposited by the nonthermal electrons may be greater. Emslie (2003) shows that the temperature of the target plasma limits the energy that can be deposited into the plasma. The energy injected into the plasma is significantly less than the electron energy computed above a low-energy cutoff if the cutoff energy is less than $5kT$, where $T$ is the temperature of the target plasma. Taking the temperature of the target plasma to be equal to or less than the temperatures we derived from the spectral fits, the low-energy cutoffs derived here all exceed $5kT$. Therefore, the computed injection energies are accurate unless undetected higher temperatures are present in the interaction region. Using our derived temperatures and the results of Emslie, we can compute the maximum energy these electrons might have injected into the flare plasma. We find this to be $4 \times 10^{34}$ erg, well above the maximum total energy that has been deduced previously for even the largest solar flares.

5. Conclusions

The RHESSI spectra presented and analyzed here are the most detailed hard X-ray spectra ever obtained for a large flare. Although these spectra are well fitted by isothermal (exponential) and double power-law photon distributions, fitting these spectra with the bremsstrahlung computed from model electron distributions is an important part of the analysis of these spectra. The electron distributions allow a more physical interpretation of the data and smooth out the unphysically sharp break in the double power-law photon spectrum. Even fits with a double power-law electron distribution, however, show systematic residuals at the level of a few percent, as in Fig. 3b. Understanding these residuals will also be an important part of the analysis of RHESSI spectra.

The July 23 flare hard X-ray spectral data provide support for the longstanding impression that the energy in accelerated electrons is a major part of the energy released in many if not all flares. Our result for the energy injected by nonthermal electrons depends, however, on our nonthermal, thick-target interpretation of the double power-law fits. One compelling alternative is that the X-ray emission observed in the early rise phase of the flare (before 00:26:00 UT) is, at least in part, thin-target bremsstrahlung from the corona (Lin et al. 2003). The extended size of the X-ray source at this time is suggestive of this interpretation. Another possibility is that the emission is from a multithermal plasma, but high temperatures would be required for this interpretation. A study of these alternatives requires additional modeling beyond the scope of this paper.

The information extracted from these spatially integrated spectra can only be fully appreciated and understood through comparison with RHESSI images and imaged spectra,
and with related observations of the flare. A synthesis and discussion of the overall flare data is contained in Lin et al. (2003).

This work was supported in part by the RHESSI Project and the NASA Sun-Earth Connection program. We thank Sally House for translating the bremsstrahlung codes from Fortran into IDL, and Paul Bilodeau for his help with the SPEX software and with integrating the bremsstrahlung codes with the SPEX software. We thank Brian Dennis for his comments on the manuscript. This work would not have been possible without the dedicated efforts of the entire RHESSI team.
